## Abstract

066

The goal of this work is to localize a query photograph by finding other images depicting the same place in a large geotagged image database. The contributions of this work are three fold. First, we learn a discriminative yet compact descriptor of each image in the database. This is achieved by applying exemplar support vector machine (e-SVM) learning to compact Fisher vector descriptors extracted from database images. Second, we analyze the exemplar support vector machine objective and show that the learnt hyperplane can be interpreted as a new descriptor that replaces the original positive example and is re-weighted to increase its separation from the negative data. Third, based on this analysis we demonstrate that the learnt and re-normalized descriptor could be directly used for matching, thus avoiding the need for expensive and tedious calibration typically needed for exemplar support vector machine methods. Place recognition results are shown on two image datasets of Google street-view images from Pittsburgh and demonstrate the learnt representation consistently improves over the standard Fisher vector descriptors at different target dimensions.

In this work we build on the method of Gronat *et al.* [12] who represent each image in the database by a per-location classifier that is trained to discriminate each place from other places in the database. At query time, the query image is classified by all per-location classifiers and assigned to a place with the highest classification score. The training of each classifier is performed using the per-exemplar support vector machine (e-SVM) [22], which takes the positive image as a single positive example and other far away images in the database as negative examples. The exemplar SVM is well suited for this task as street-level image collections typically contain only one or at most hand-full of images depicting the same place. The intuition is that the exemplar SVM can learn the important features that distinguish the particular place from other similar places in the database. While the results of [12] are promising they suffer from two important drawbacks. First, the learnt place specific representation is not compact, which prohibits its application to planet-scale street-level collections that are now becoming available [16]. Second, the per-exemplar classifiers require careful and time-consuming calibration.

In this work we address both these issues. First, we apply the exemplar SVM training to compact Fisher vector [14, 24] image descriptors, which results in a *discriminative* yet *compact* representation of each image in the database. Second, to avoid the expensive classifier calibration, we analyze the exemplar SVM cost and show that the learnt hyperplane can be interpreted as a new descriptor that replaces the original positive example and is re-weighted to increase its separation from the negative data. As a result of this analysis, we demonstrate that after an appropriate normalization of the new re-weighted descriptor no further calibration is necessary. We show improved results on place recognition using learnt compact Fisher vector descriptors [14] of different dimensionality.

## 1. Introduction

091

092

093

The goal of this work is to localize a query image by matching to a large database of geotagged street-level imagery. This is an important problem with practical applications in robotics, augmented reality or navigation. This task is however very difficult. It is hard to distinguish different places, e.g. streets in a city, from each other. The imaged appearance of a place can change drastically due to factors such as viewpoint, illumination or even changes over time. Finally, with the emergence of planet-scale geotagged image collections, such as Google Street-view, the image databases are becoming very large. We estimate a single country like France is covered by more than 60 million street-level panoramas. Hence the fundamental challenge in place recognition lies now in designing robust, discriminative yet compact image representations.

103

104

105

106

107

**Large-scale visual place recognition** The visual localization problem is typically treated as large-scale instance-level retrieval [6, 4, 12, 17, 27, 34, 35], where images are represented using local invariant features [21] aggre-

108 gated into the bag-of-visual-words [5, 32] representation.  
 109 The image database can be further augmented by 3D point  
 110 clouds [16], automatically reconstructed by large-scale  
 111 structure from motion (SfM) [1, 16], which enables accurate  
 112 prediction of query image camera position [20, 25].  
 113 In this work we investigate learning a discriminative  
 114 representation using the compact Fisher vector descriptors [15].  
 115 Fisher vector descriptors have shown excellent place recog-  
 116 nition accuracy [34]. In this work we further improve their  
 117 performance by discriminative learning.  
 118

119  
 120 **Fisher vector image representations** Fisher vector im-  
 121 age representations have recently demonstrated excellent  
 122 performance for a number of visual recognition tasks [3,  
 123 15, 18, 30]. They are specially suited for retrieval applica-  
 124 tions since they are robust to image appearance variations  
 125 and capture richer image statistics than the simple bag-of-  
 126 visual-words (BOW) aggregation. However, the raw ex-  
 127 tracted Fisher vectors are typically high-dimensional, e.g.  
 128 with 32,768 non-sparse dimensions, which is impractical  
 129 for large-scale visual recognition and indexing applications.  
 130 Hence, their dimensionality is often reduced by principal  
 131 component analysis (PCA) and further quantized for effi-  
 132 cient indexing using, e.g. a product quantizer [15]. Other  
 133 recent work has demonstrated improved performance in a  
 134 face recognition application by finding discriminative pro-  
 135 jection using a large amount of training face data [30].  
 136 Our work is complementary to these methods as it oper-  
 137 ates on the projected low-dimensional descriptor and further  
 138 learns discriminative re-weighting of the descriptor specific  
 139 to each image in the database using per-exemplar support  
 140 vector machine [22].  
 141

142  
 143 **Per-exemplar support vector machine** The exemplar  
 144 support vector machine (e-SVM) has been used in a number  
 145 of visual recognition tasks including category-level recog-  
 146 nition [22], cross-domain retrieval [29], scene parsing [33],  
 147 place recognition [12] or as an initialization for more com-  
 148 plex discriminative clustering models [8, 31]. The main  
 149 idea is to train a linear support vector machine (SVM) clas-  
 150 sifier from a single positive example and a large number of  
 151 negatives. The intuition is that the resulting weight vector  
 152 will give a higher weight to the discriminative dimensions  
 153 of the positive training data point and will down weight  
 154 dimensions that are non-discriminative with respect to the  
 155 negative training data. A key advantage is that each per-  
 156 exemplar classifier can be trained independently and hence  
 157 the learning can be heavily parallelized. The per-exemplar  
 158 training brings however also an important drawback. As  
 159 each classifier is trained independently a careful calibration  
 160 of the resulting classifier scores is required [12, 22].  
 161

162 **Contributions** The contributions of this work are three-  
 163 fold. First, we analyze the exemplar support vector machine  
 164 objective and show that the learnt hyperplane can be inter-  
 165 preted as a new descriptor that replaces the original positive  
 166 example and is re-weighted to increase its separation from  
 167 the negative data. Second, we demonstrate that after an ap-  
 168 propriate normalization of the new re-weighted descriptor  
 169 no further calibration is necessary. Third, we apply e-SVM  
 170 training to compact Fisher vector descriptors for large-scale  
 171 place recognition resulting in a *discriminative yet compact*  
 172 representation of each image in the database. Place recog-  
 173 nition results are shown on a dataset of 25k images of Pitts-  
 174 burgh and demonstrate the learnt representation consistently  
 175 improves over the standard Fisher vector descriptors at dif-  
 176 ferent target dimensions.  
 177

### 3. Learning compact place descriptors using per-exemplar SVM

178 Each database image  $j$  is represented by its L2-  
 179 normalized Fisher vector  $\Phi_j$ . The goal is to learn a set  
 180 of new L2-normalized Fisher vectors  $\Psi_j$ , one per each  
 181 database image, such that at query time, given the Fisher  
 182 vector  $\Phi_q$  of an unknown query image, we retrieve the  
 183 database image depicting the same location by finding the  
 184 image  $j^*$  with the highest score measured by a dot product  
 185

$$j^* = \arg \max_j \Phi_q^T \Psi_j. \quad (1)$$

186 In other words, the aim is to replace each original database  
 187 Fisher vector  $\Phi_j$  with a new vector  $\Psi_j$  that is more dis-  
 188 criminative in the sense of separation from descriptors of  
 189 images depicting other places. Inspired by [12], we in-  
 190 vestigate applying the exemplar support vector machine (e-  
 191 SVM) [22] for this task. e-SVM learns a linear classifier  
 192  $w_j^T \Phi + b_j$  given the descriptor  $\Phi_j^+$  of place  $j$  as a single  
 193 positive example (with target label +1) and a large number  
 194 of negative descriptors  $\mathcal{N}_j$  from other places in the database  
 195 (with target labels -1). The intuition of the exemplar SVM  
 196 training [22] is that the learnt weight vector  $w_j$  will give a  
 197 higher weight to the dimensions of the descriptor that are  
 198 discriminative and will down-weight dimensions that are  
 199 non-discriminative with respect to the negative training data  
 200 collected from other far-away places. The optimal  $w_j$  and  
 201  $b_j$  are obtained by minimizing the following objective  
 202

$$\|w_j\|^2 + C_1 \cdot h(w_j^T \Phi_j^+ + b_j) + C_2 \sum_{\Phi \in \mathcal{N}_j} h(-w_j^T \Phi - b_j), \quad (2)$$

203 where  $\Phi_j^+$  is the descriptor of the place  $j$  as the positive data  
 204 point,  $\Phi$  are Fisher descriptors from negative training data  
 205  $\mathcal{N}_j$  and  $h$  is the hinge loss,  $h(y) = \max(1 - y, 0)$ . Note  
 206 that the first term in (2) is the regularizer, the second term  
 207

216 is the loss on the positive data weighted by scalar parameter  
 217  $C_1$  and the third term is the loss on the negative data  
 218 weighted by scalar parameter  $C_2$ . The objective is convex  
 219 and can be minimized with respect to  $w_j$  and  $b_j$  using stan-  
 220 dard software packages such as [10]. A key advantage is  
 221 that the per-exemplar classifier for each place can be trained  
 222 independently and hence the learning can be heavily paral-  
 223 lelized. The downside of the independent training for each  
 224 positive example is that the resulting scores have to be cal-  
 225 brated with respect to each other on additional data [12, 22].  
 226

### 227 3.1. Analysis of per-exemplar SVM objective

228 In this section, we analyze the exemplar SVM objec-  
 229 tive (2) and show the learnt and *re-normalized* weight vector  
 230  $w_j$  can be interpreted as a new descriptor  $\Psi_j$  that replaces  
 231 the original positive training descriptor  $\Phi_j^+$ . In particular,  
 232 we show first that when the weight  $C_2$  of the negative data  
 233 in objective (2) goes to zero and the learnt  $\Psi_j$  is identical to  
 234 the original positive training data point  $\Phi_j^+$ . Second, when  
 235  $C_2 > 0$ , the learnt  $\Psi_j$  moves away from the positive  $\Phi_j^+$  to  
 236 increase its separation from the negative data. Details are  
 237 given next.

238 **Case I:**  $C_2 \rightarrow 0$ . The goal is to show that when the weight  
 239  $C_2$  of the negative data in objective (2) goes towards zero  
 240 the resulting hyperplane vector  $w_j$  is parallel with the pos-  
 241 itive training descriptor  $\Phi_j^+$ . When  $w_j$  is normalized to  
 242 have unit L2 norm the two vectors are identical. First, let  
 243 us decompose  $w$  into parallel and orthogonal part with  
 244 respect to the positive training data point  $\Phi^+$  (in the following  
 245 we omit index  $j$  for brevity), i.e.  $w = w^\perp + w^\parallel$ , where  
 246  $(w^\perp)^T \Phi^+ = 0$ . Next, we observe that when the weight of  
 247 the negative data diminishes ( $C_2 \rightarrow 0$ ), any non-zero com-  
 248 ponent  $w^\perp$  will increase the value of the objective. As a  
 249 result, for  $C_2 \rightarrow 0$  the objective is minimized by  $w^\parallel$ , i.e.  
 250 the optimal  $w$  is parallel with  $\Phi^+$ .

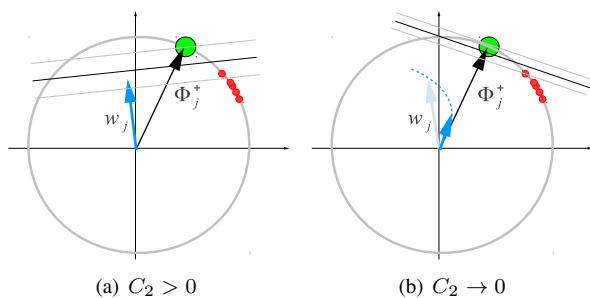

251 In detail, for  $w = w^\perp + w^\parallel$  the objective (2) can be  
 252 written as

$$\begin{aligned} 253 \|w^\perp + w^\parallel\|^2 + C_1 \cdot h((w^\perp + w^\parallel)^T \Phi^+ + b) \\ 254 + C_2 \sum_{\Phi \in \mathcal{N}} h(-(w^\perp + w^\parallel)^T \Phi - b). \end{aligned} \quad (3)$$

255 Note that the orthogonal part  $w^\perp$  does not change the value  
 256 of the second term in (3) because  $(w^\perp + w^\parallel)^T \Phi^+ =$   
 257  $(w^\parallel)^T \Phi^+$ , and hence (3) reduces to

$$\begin{aligned} 258 \|w^\perp + w^\parallel\|^2 + C_1 \cdot h(w^\parallel T \Phi^+ + b_j) \\ 259 + C_2 \sum_{\Phi \in \mathcal{N}} h(-(w^\perp + w^\parallel)^T \Phi - b). \end{aligned} \quad (4)$$

260 In the limit case as  $C_2 \rightarrow 0$  any non-zero component  $w^\perp$   
 261 will increase the value of the objective (4). This can be

262 **Figure 1: An illustration of the effect of decreasing pa-  
 263 rameter  $C_2$  in the exemplar support vector machine ob-  
 264 jective.** The positive exemplar  $\Phi_j^+$  is shown in green. The  
 265 negative data points are shown in red. All training data is  
 266 L2 normalized to lie on a hyper-sphere. (a) For  $C_2 > 0$ , the  
 267 normal  $w_j$  of the optimal hyper-plane moves away from the  
 268 direction given by the positive example  $\Phi_j^+$  in a manner that  
 269 reduces the loss on the negative data. (b) As the parameter  
 270  $C_2$  decreases the learnt  $w_j$  becomes parallel to the positive  
 271 training example  $\Phi_j^+$  and its magnitude  $\|w_j\|$  goes to 0.

272 seen by noting that the third term vanishes when  $C_2 \rightarrow 0$   
 273 and hence the objective is dominated by the first two terms.  
 274 Further, the second term in (4) is independent of  $w^\perp$ . Fi-  
 275 nally, the first term will always increase for any non-zero  
 276 value of  $w^\perp$  as  $\|w^\perp + w^\parallel\|^2 \geq \|w^\parallel\|^2$  for any  $w^\perp \neq 0$ .

277 As a result, in the limit case when  $C_2 \rightarrow 0$  the optimal  
 278  $w$  is parallel with  $\Phi^+$ . Note also, that when  $C_2$  is exactly  
 279 equal to zero,  $C_2 = 0$ , the optimal  $w$  vanishes, i.e. the  
 280 objective (4) is minimized by trivial solution  $\|w\| = 0$  and  
 281  $b_j = -1$ . The effect of decreasing the parameter  $C_2$  is  
 282 illustrated in figure 1.

283 **Case II:**  $C_2 > 0$ . When the weight  $C_2$  of the negative  
 284 data in the objective (4) increases the direction of the  
 285 optimal  $w$  will be different from  $w^\parallel$  and will change to take  
 286 into account the loss on the negative data points. Explicitly  
 287 writing the hinge-loss  $h(x) = \max(1 - x, 0)$  in the last  
 288 term of (4), we see that  $w$  will move in the direction that re-  
 289 duces  $\sum_{\Phi \in \mathcal{N}} \max(1 + w^T \Phi + b, 0)$ , i.e. that reduces the  
 290 dot product  $w^T \Phi$  on the negative examples that are active  
 291 (support vectors).

### 292 3.2. Interpreting normalized $w$ as a new descriptor

293 The above analysis demonstrates that as  $C_2$  decreases  
 294 the normal of the optimal hyperplane  $w$  that separates the  
 295 positive exemplar  $\Phi^+$  from negative data becomes parallel  
 296 with  $\Phi^+$ , as shown in figure 1. As  $C_2$  increases, the normal  
 297  $w$  of the optimal hyper-plane moves away from the direction  
 298 given by the positive example  $\Phi^+$  in a manner that reduces  
 299 the loss on the negative data. This suggests that the learnt  $w$

324 could be interpreted as a modified positive example  $\Phi^+$ , re-  
 325 weighted to emphasize directions that separate  $\Phi^+$  from the  
 326 negative data. As discussed above  $w$  is not normalized. As  
 327 we wish to measure the similarity between descriptors by  
 328 (the cosine of) their angle given by equation (1), additional  
 329 normalization of the learnt  $w$  is necessary. Hence we define  
 330 the new descriptor  $\Psi_j$  as the normalized hyperplane normal  
 331  $w_j$

$$\Psi_j = \frac{w_j}{\|w_j\|}. \quad (5)$$

## 335 4. Experimental evaluation

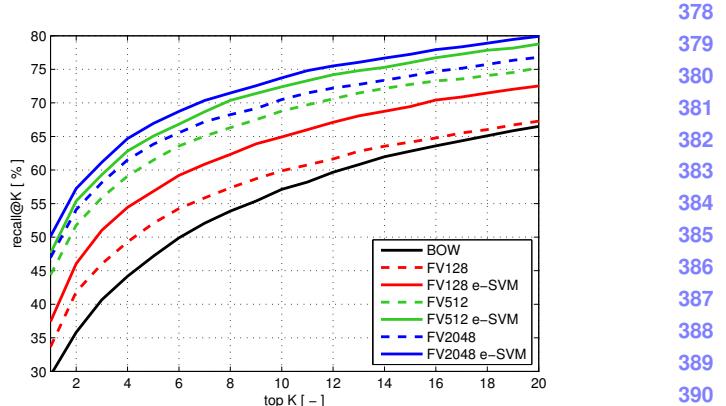

336 In this section we first describe the experimental set-up,  
 337 then we give implementation details, and finally report re-  
 338 sults of the proposed approach on two datasets where we  
 339 compare performance with raw Fisher vector matching and  
 340 several baselines methods.

### 342 4.1. Experimental set-up

343 We perform experiments on a database of Google Street  
 344 View images of Pittsburgh downloaded from the Internet.  
 345 The data contains panoramas covering roughly an area of  
 346  $1.3 \times 1.2 \text{ km}^2$ . Similar to [4], for each panorama we  
 347 generate 12 overlapping perspective views corresponding  
 348 to two different elevation angles to capture both the street-  
 349 level scene and the building façades, resulting in a total of  
 350 24 perspective views each with  $90^\circ$  FOV and resolution of  
 351  $960 \times 720$  pixels. For evaluation we have used two versions  
 352 of this data. The first one was obtained from the authors  
 353 of [12] (25k images). In the second version we download  
 354 additional images to increase the dataset size to 55k images.  
 355 As a query set with known ground truth GPS positions, we  
 356 use the 8999 panoramas from the Google Street View re-  
 357 search dataset. This dataset covers approximately the same  
 358 area, but has been captured at a different time, and depicts  
 359 the same places from different viewpoints and under differ-  
 360 ent illumination conditions. For each test panorama, we  
 361 generate a set of perspective images as described above. Fi-  
 362 nally, we randomly select out of all generated perspective  
 363 views a subset of 4k images, which is used as a test set to  
 364 evaluate the performance of the proposed approach. Since  
 365 all the query images have associated GPS location we can  
 366 compute their spatial distance from the database images re-  
 367 turned by the matching method. We consider a query image  
 368 to be correctly localized if the retrieved database image lies  
 369 within a perimeter of 20m from the location of the query.  
 370

### 371 4.2. Implementation details

372 We first extract rootSIFT descriptors [2] for each im-  
 373 age. Following [15] we project the 128-dimensional SIFT  
 374 descriptors to 64 dimensions using PCA. The projection  
 375 matrix is learnt on a set of descriptors from 5,000 ran-  
 376 domly selected database images. This has also the effect  
 377

392 **Figure 2: Evaluation on Pittsburgh 25k [12] dataset.** The  
 393 fraction of correctly recognized queries (recall@K, y-axis)  
 394 vs. the number of top  $K$  retrieved database images for  
 395 different Fisher vector dimensions. The learnt descriptors  
 396 by the proposed method (FV e-SVM) consistently improve  
 397 over the raw Fisher vector descriptors across the whole  
 398 range of  $K$  and all dimensions.

400 of decorrelating the SIFT descriptor. The 64-dimensional  
 401 SIFT descriptors are then aggregated into Fisher vectors us-  
 402 ing a Gaussian mixture model with  $N = 256$  components,  
 403 which results in a  $2 \times 256 \times 64 = 32,768$ -dimensional  
 404 descriptor for each image. The Gaussian mixture model  
 405 is learnt from descriptors extracted from 5,000 randomly  
 406 sampled database images. The high-dimensional Fisher  
 407 vector descriptors are then projected down to dimension  
 408  $d \in \{128, 512, 2048\}$  using PCA learnt from all avail-  
 409 able images in the database. The resulting low dimensional  
 410 Fisher vectors are then re-normalized to have unit L2-norm,  
 411 which we found to be important in practice.

413 **Learning parameters and training data.** To learn the  
 414 exemplar support vector machine for each database image  
 415  $j$ , the positive and negative training data are constructed as  
 416 follows. The *negative training set*  $\mathcal{N}_j$  is obtained by: (i)  
 417 finding the set of images with geographical distance greater  
 418 than 200m; (ii) sorting the images by decreasing value of  
 419 similarity to image  $j$  measured by the dot product between  
 420 their respective Fisher vectors; (iii) taking the top  $N = 500$   
 421 ranked images as the negative set. In other words, the neg-  
 422 ative training data consists of the hard negative images, i.e.  
 423 those that are similar to image  $j$  but are far away from its  
 424 geographical position, hence, cannot have the same visual  
 425 content. The *positive training set*  $\mathcal{P}_j$  consist of the original  
 426 Fisher vector  $\Phi_j$  of the image  $j$ . For the SVM training we  
 427 use libsvm [10]. We use the same  $C_1$  and  $C_2$  parameters  
 428 for all per-exemplar classifiers, but find the optimal value of  
 429 the parameters for each dimensionality of the Fisher vector  
 430 by a grid search evaluating performance on a held out set.

We observe that for different Fisher vector target dimensions the optimal value of parameter  $C_1$  is quite stable (typically  $C_1 = 1$ ) while the optimal parameter for  $C_2$  varies between  $10^{-6}$  to  $10^{-1}$ . To learn the new image representation for each database image  $j$  we: (i) learn SVM from  $\mathcal{P}_j$  and  $N_j$  (see above); (ii)  $L2$  normalize the learned  $w_j$  using equation (5); and (iii) use this re-normalized vector as the new image descriptor  $\Psi_j$  for image  $j$ . At query time we compute the Fisher vector  $\Phi_q$  of the query image and measure its similarity score to the learnt descriptors  $\Psi_j$  for each database image by equation (1).

### 4.3. Results

For each database (Pittsburgh 25k and Pittsburgh 55k) we compare results of our method (FV e-SVM) to two baselines: standard bag-of-visual-words baseline (BOW) and raw Fisher vector matching without learning (FV).

We perform experiments on several target Fisher vector dimensions  $d \in \{128, 512, 2048\}$ . For each method we measure performance using the percentage of correctly recognized queries (Recall) similarly to, e.g., [4, 17, 26]. The query is correctly localized if at least one of the top  $K$  retrieved database images is within 20 meters from the ground truth position of the query. Results are shown for different values of  $K$  in table 1. For the Pittsburgh 25k we also show results in the form of a curve in figure 2. The results clearly demonstrate the benefits of the learnt descriptors with respect to the standard Fisher vectors for all target dimensions and lengths of shortlist  $K$ . The benefits of discriminative learning are specially prominent for low-dimensional compact descriptors ( $d = 128$ ). The proposed method also significantly outperforms the bag-of-visual-words baseline. Figure 4 shows examples of place recognition results.

**Comparison to other methods.** On the Pittsburgh 25k database, we compare performance of our learnt discriminative descriptors to the methods of [12] and [17], who report on the same testing data top  $K = 1$  recall of 36.5% and 41.9%, respectively (results taken from [12]). Our method outperforms [17] already for dimension  $d = 128$  (37.8%) and [12] for dimension  $d = 512$  (47.6%). Furthermore, note that [12, 17] are based on a bag-of-visual-words representation, which typically needs to store between 1000-2000 non-zero visual words per image, which is significantly more than our learnt 128 or 512 dimensional descriptor.

**Memory complexity analysis.** Figure 3 compares the performance of the learnt discriminative descriptor (FV eSVM) to the raw Fisher vectors (FV) for different target dimensions. The results demonstrate that for a given level of accuracy (y-axis) our method learns a more compact (lower-dimensional) representation (x-axis). For example,

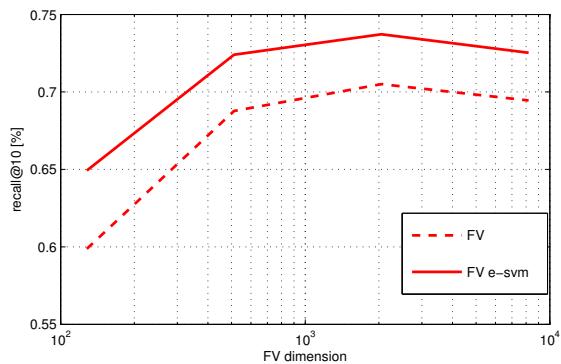

Figure 3: **Memory complexity analysis.** The fraction of correctly localized queries at the top 10 retrieved images (y-axis) for different Fisher vector dimensions (x-axis). The learnt descriptors by our method (FV e-SVM) clearly outperform the raw Fisher vector descriptors (FV) for all dimensions. Note that for a certain level of performance (y-axis) the proposed method learns a more memory efficient (lower dimensional, x-axis) descriptor.

our learnt 128-dimensional descriptor achieves a similar accuracy (around 65%) to the 256-dimensional raw Fisher descriptor essentially reducing the memory complexity to 50% for the same level of performance. Note that similar to [15], we observe decrease in performance at high-dimensions for both the baseline and our method.

## 5. Conclusions

We have shown that a discriminative yet compact image representation for place recognition can be learnt using the exemplar support vector machine applied to Fisher vector image descriptors without the need for expensive and tedious calibration typical for other exemplar support vector machine methods. Our results show significant gains in place recognition performance compared to raw Fisher vector matching as well as other baselines. Our work opens up the possibility of learning a compact and discriminative representation using other descriptors such as HOG [7] or the recently developed convolutional neural network features [9, 19, 23, 28] as well as extending the analysis to other cost functions [11, 13].

Figure 4: **Examples of correctly and incorrectly localized queries for the learnt Fisher vector representation.** Each example shows a query image (left) together with correct (green) and incorrect (red) matches from the database obtained by the learnt Fisher vector representation *w-norm* method (top) and the standard Fisher vector baseline (bottom) for dimension 128. Note that the proposed method is able to recognize the place depicted in the query image despite changes in viewpoint, illumination and partial occlusion by other objects (trees, lamps) and buildings. Note that the baseline methods often finds images depicting the same buildings but in a distance whereas our learnt representation often finds a closer view better matching the content of the query.
